The growth of snow crystals is dependent on the temperature and saturation of the environment. In the case of dendrites, Reiter’s local two-dimensional model provides a realistic approach to the study of dendrite growth. In this paper we obtain a new geometric rule that incorporates interface control, a basic mechanism of crystallization that is not taken into account in the original Reiter model. By defining two new variables, growth latency and growth direction, our improved model gives a realistic model not only for dendrite but also for plate forms.

I. INTRODUCTION

Snowflake growth is a specific example of crystallization: how crystals grow and create complex structures. Because crystallization corresponds to a basic phase transition in physics, and crystals make up the foundation of several major industries, studying snowflake growth helps gaining understanding of how molecules condense to form crystals. This fundamental knowledge may help fabricate novel types of crystalline materials.

Snowflakes exhibit a rich combination of characteristic symmetry and complexity. The sixfold symmetry is a result of the hexagonal structure of the ice crystal lattice, and the complexity comes from the random motion of individual snow crystals falling through the atmosphere.

Scientific studies of snowflakes can be categorized into two main types. The first approach takes a macroscopic view by observing natural snowflakes in a variety of morphological environments characterized by temperature, pressure, and vapor density (e.g., Refs. [3–5]). The second type takes a microscopic view and investigates the basic physical mechanisms governing the growth of snowflakes (e.g., see Ref. [1]). While some aspects of snowflake growth (e.g., the crystal structure of ice) are well understood, many other aspects such as diffusion limited growth are at best understood at a qualitative level.

Another approach in which snowflake growth is numerically simulated to produce images with mathematical models derived from physical principles is through computer modeling (e.g., see Refs. [6–11]). By comparing computer generated images with actual snowflakes, one can correlate the mathematical models and their parameters with physical conditions. While computer modeling can generate snowflake images that successfully capture some basic features of actual snowflakes, certain fundamental features of snowflake growth are not well understood, and so far there has been only limited analysis of these computer models in the main types. The first approach takes a macroscopic view by observing natural snowflakes in a variety of morphological environments characterized by temperature, pressure, and vapor density (e.g., Refs. [3–5]). The second type takes a microscopic view and investigates the basic physical mechanisms governing the growth of snowflakes (e.g., see Ref. [1]). While some aspects of snowflake growth (e.g., the crystal structure of ice) are well understood, many other aspects such as diffusion limited growth are at best understood at a qualitative level.

Another approach in which snowflake growth is numerically simulated to produce images with mathematical models derived from physical principles is through computer modeling (e.g., see Refs. [6–11]). By comparing computer generated images with actual snowflakes, one can correlate the mathematical models and their parameters with physical conditions. While computer modeling can generate snowflake images that successfully capture some basic features of actual snowflakes, certain fundamental features of snowflake growth are not well understood, and so far there has been only limited analysis of these computer models in the literature (e.g., Refs. [6,7,12–14] and references therein). One of the key challenges has been that the snowflake growth models consist of a large set of PDEs, and as in many chaos theoretic models, rigorous study is difficult.

In this paper we analyze snowflake growth simulated by the computer models. The models that have been considered in the past are in essence chaos theoretic models, which is why they successfully capture the real world phenomena but prove to be notoriously difficult to analyze rigorously. In particular, two mechanisms studying the instability of the crystal have been studied in the past: the Mullins-Sekerka instability, and the facet instability for a hexagonal prism snow crystal (e.g., see Refs. [12,15] and references therein). Some models, e.g., proposed in Refs. [6,7,13], are highly detailed and sophisticated and meant to almost exactly match snow crystal growth, while others, e.g., Reiter’s model [10], are relatively simple meant for understanding, thought experiments and analysis. In this paper we study Reiter’s model using a combined approach of mathematical analysis and numerical simulation. It should be pointed out that the goal of this paper is to provide mathematical treatment of the computational model.

The model, however, is an artificial one and does not include the actual growth processes. As such, the paper is not intended to further the understanding the formation mechanism of actual snowflake patterns.

After reviewing Reiter’s model in Sec. II, in Sec. III we divide a snowflake image into main branches and side branches and define two new variables (growth latency and growth direction) to characterize the growth patterns. In Sec. IV we derive a closed form solution of the main branch growth latency using a one-dimensional linear model and compare it with the simulation results using the hexagonal automata. Then in Sec. V we discover a few interesting patterns of the growth latency and direction of side branches. On the basis of the analysis and the principle of surface free energy minimization, in Sec. VI we enhance Reiter’s model and thus obtain realistic results both for dendrites and plate forms. We summarize our contributions and present a few future work directions in Sec. VII.

II. AN OVERVIEW OF REITER’S MODEL

Reiter’s model is a hexagonal automata which can be described as follows. Given a tessellation of the plane into hexagonal cells, each cell $z$ has six nearest neighbors. We shall denote by $s_{i}(z) \in \mathbb{R}_{>0}$ the state variable of cell $z$ at time...
Underlying mathematical models: neighbors according to two local update rules that reflect the state of a cell evolves as a function of the states of its nearest and diffusion coefficients, nonreceptive.

The underlying physical principle of Eq. (3) is the diffusion equation

\[ \frac{\partial u}{\partial t} = a \nabla^2 u, \]

where \( a \) is a constant. Indeed, Eq. (3) is the discrete version of Eq. (4) on the hexagonal lattice, and it states that a cell \( z \) retains \((1 - \alpha/2)\) fraction of \( u^{-}_{\tau}(z) \), uniformly distributes the remaining to its six neighbors, and receives \( \alpha/12 \) fraction from each neighbor. The total amount of \( u(z) \) would be conserved within the entire system, except that a real world simulation consists of a finite number of contiguous cells. The cells at the edge of the simulation setup are referred to as edge cells, in which one sets \( u^{+}_{\tau}(z) \) := \( \beta \). Thus, water is added to the system via the edge cells in the diffusion process. Combining the two intermediate variables, one obtains

\[ s_{t+1}(z) := u^{+}_{\tau}(z) + v_{\tau}(z). \]

By varying the parameters \( \alpha, \beta, \gamma \) in Reiter’s model one can generate certain geometric forms of snowflakes observed in nature (Fig. 3).

III. GENERAL GEOMETRIC PROPERTIES

In what follows, we give new descriptions of snowflake growth and analyze them with a combined approach of mathematical analysis and numerical simulation by considering a coordinate system of cells as in Fig. 4(a). A cell \( z \) is represented by its coordinate \((i,j)\), for \( i, j \in \mathbb{Z} \), with the origin \( \mathcal{O} = (0,0) \). Since there is a sixfold symmetry, we focus on only one-twelfth of the cells, marked as dark dots, for which \( j \geq i \geq 0 \).

The images in Fig. 3 show that a crystal consists of six main branches that grow along the lattice axes, and numerous side branches that grow from the main branches in a seemingly random manner. The main and side branches exhibit a rich combination of characteristic symmetry and complexity which
we shall study through the rate of water accumulation of a cell \( z \), defined by

\[
\Delta s_i(z) = s_{i+1}(z) - s_i(z). 
\]

At any time the set of all the R cells is connected. Moreover since a frozen cell is surrounded by receptive cells and does not accumulate water via diffusion, and since water flows from nonreceptive cells to boundary cells, one has that the rate of water accumulation \( \Delta s_i(z) \) of a cell satisfies the following general geometric properties:

(A) For an NR cell \( z \), one has \( 0 < s_i(z) \leq \beta \) and \( \Delta s_i(z) \leq 0 \). Suppose that an NR cell \( z \) is surrounded by \( R \) cells and disconnected from the \( E \) cells. If \( \gamma > 0 \), there exists \( t_0 > 0 \) such that \( s_i(z) \geq 1 \) (i.e., a time \( t_0 \) in which the cell becomes frozen); otherwise the NR cell will permanently remain nonreceptive and never become frozen.

(B) For a \( B \) cell \( z \) the quantity \( \Delta s_i(z) \) is the sum of \( \gamma \) and diffusion. If \( \gamma > 0 \), there exists \( t_0 > 0 \) such that \( s_i(z) \geq 1 \); otherwise, if cell \( z \) is surrounded by a set of \( F \) cells and disconnected from the \( E \) cells, then as in (A), the cell will never become frozen:

\[
\lim_{t \to \infty} s_i(z) < 1. 
\]

(C) For an \( F \) cell \( z \), one has \( \Delta s_i(z) = \gamma \).

(D) The state variable is \( s_i(z) = \beta \) only for \( z \) an \( E \) cell.

Thus, for an NR cell to become frozen, the cell goes through two stages of growth. First, the NR cell loses vapor to other cells due to diffusion, as in (A). Subsequently, it becomes a \( B \) cell and accumulates water via diffusion and addition, as in (B), until it becomes frozen and sees no benefit of diffusion, as in (C). Becoming a \( B \) cell is a critical event between the two stages.

We focus on the second stage and define two new variables to characterize growth patterns.

**Definition 3.** The time to be frozen of a cell \( z \) is denoted by \( T(z) \) and defined by the condition \( s_{T(z)}(z) \geq 1 \), and \( s_i(z) < 1 \) for \( t < T(z) \). Similarly, we define \( B(z) \) as the first time to be boundary. Finally, growth latency is denoted by \( L(z) \) and defined by \( L(z) := T(z) - B(z) \).

A cell becomes a \( B \) cell as one of its neighboring cells has just become an \( F \) cell, and thus it is useful to make the following definition in terms of redistribution of water.

**Definition 4.** Denote by \( z_{sd} \) a destination cell, and by \( z_s \) a source cell. Then the growth direction of cell \( z_{sd} \) is denoted by \( g(z_{sd}) \) and defined as the orientation of \( z_s \) with respect to \( z_{sd} \), where the angle is with respect to the horizontal axis. The source-destination cell relationship shall be denoted by \( S(z_{sd}) := z_s \).

As shown in Fig. 4(b), the angle is given relative to the horizontal direction in the coordinate system and satisfies

\[
g(z_{sd}) \in \{+30^\circ, -30^\circ, +90^\circ, -90^\circ, +150^\circ, -150^\circ\}. 
\]

Note that while the growth of \( z_{sd} \) is traced back to a unique \( z_s \), a source cell may correspond to multiple destination cells.

## IV. GROWTH OF MAIN BRANCHES

Consider cells \( (i,j) \) where \( i + j = K \) for a fixed \( K \). These cells are all \( K \) sites away from the origin \((0,0)\) on the grid. The main branch growth pattern is such that \( T(0,K) \leq T(i,j) \) and

\[
T\left(\frac{K}{2}, \frac{K}{2}\right) \geq T(i,j) \quad \text{for even } K, \\
T\left(\frac{K-1}{2}, \frac{K-1}{2}\right) \geq T(i,j) \quad \text{for odd } K. 
\]

Along the lattice \( j \) axis, one has \( g(0,j) = -90^\circ \) for all \( j \). Hence, the snowflake growth is fastest along a lattice axis, which represents a main branch, and is the slowest along the \( 30^\circ \)-offset lattice axis.

We next develop a model to calculate the growth latency \( L(0,j) \). As cell \((0,j)\) becomes frozen, cell \((0,j+1)\) becomes a boundary cell. Hence the first time to be boundary \( B(0,j+1) = T(0,j) \), and thus one can calculate \( T(0,j) \) as

\[
T(0,j) = T(0,0) + \sum_{k=1}^{j} L(0,k). 
\]

In order to gain analytical understanding, we first study a one-dimensional model. Consider a line of consecutive cells \( z_0, z_1, \ldots, z_N \), where \( Z_N \) is the edge cell. Initially cell \( O \) is frozen. We focus on the growth period \([B(k),T(k)]\) in which cells \( z_0, z_1, \ldots, z_{k-1} \) are frozen and cell \( k \) grows from boundary to frozen. Since Eq. (3) describes the diffusion dynamics of vapor being transferred from the edge cell to cell \( z_k \), and cell \( z_k \) accumulates water via addition [Eq. (2)], to derive an analytical solution, we make the following assumption which we justify shortly.

**Assumption I.** For \( t \in [B(z_k),T(z_k)] \), assume that in Eq. (3) one has

\[
u^e_i(z_i) = u^e_i(z_i),
\]

for \( k + 1 \leq i \leq N \), for \( N \) as above and \( B(z_k),T(z_k) \) as in Definition III. Therefore, the vapor distribution reaches a steady state, denoted as \( \mu(i|k) \).

From Assumption IV, we can ignore the notations of \( \pm \), and reduce Eq. (3) to the linear equation

\[
\mu(i|k) = \frac{1}{2} [\mu(i-1|k) + \mu(i+1|k)]. 
\]

Moreover, with the boundary conditions \( \mu(k|k) = 0 \) and \( \mu(N|k) = \beta \), the vapor distribution can be written in a closed form as follows:

\[
\mu(i|k) = \frac{i-k}{N-k} \beta, \quad \text{for } i = k, \ldots, N, 
\]

which graphically represents a line that connects the two boundary condition points.

We shall now explain why Assumption IV is well motivated. Suppose that the steady state distribution Eq. (8) is already
reached at $t = B(z_k)$:

$$s_{B(z_k)}(z_i) = \mu(i|k-1) = \frac{i - (k - 1)}{N - (k - 1)} \beta$$  for $i = k, \ldots, N$.

Then $s_i(z_t)$ evolves in the interval of $(B(z_k), T(z_k))$ in the following manner. For $N \gg k$, one has

$$s_{B(z_k)}(z_k) = \mu(k|k-1) = \frac{1}{(N-k+1)} \beta \approx 0.$$  

Thus it is reasonable to assume

$$L(z_k) = T(z_k) - B(z_k) \gg 1$$

because cell $z_k$ will take several simulation steps to reach $s_{T(z_k)}(z_k) \geq 1$. Moreover,

$$|s_{B(z_k)}(z_i) - \mu(i|k)| = \frac{i - (k - 1)}{N - (k - 1)} \beta - \frac{(i - k)}{(N - k)} \beta \ll 1$$

for $N \gg k$. Thus, in each simulation step for time $i \in (B(z_k), T(z_k))$, the function $s_i(z_t)$ varies only slightly and can be considered approximately constant. Hence, $u^+_i(z_k) = s_i(z_k)$. From Eq. (3) and Eq. (7), we may estimate $u^+_i(z_k)$ by

$$\hat{u}^+_i(z_k) := \alpha \cdot \frac{1}{4 N} - \frac{1}{\beta}.$$  

Moreover, since $u^-_i(z_k) = 0$ it follows that we can further estimate $\Delta s_i(z_k)$ and $L(z_k)$ by

$$\hat{\Delta s}_i(z_k) := \alpha \cdot \frac{1}{4 N - k} \beta + \gamma,$$

$$\hat{L}(z_k) := 1 - s_{B(z_k)}(z_k) \Delta \hat{s}_i(z_k) = 1 - \frac{1}{4 N - k} \beta + \gamma.$$  

In the one-dimensional model with $N = 50$, we may compare the vapor accumulation in every simulation step, as the simulation proceeds from the time when cell $k = 25$ just becomes the boundary to the time when it becomes frozen. Figure 5 compares $\Delta s_i(z_k)$ at cell $z_k$ determined by the simulation, and $\Delta \delta_i(z_k)$ predicted by Eq. (9) for time $t \in [B(z_k), T(z_k)]$. Initially $s_i(k) \ll \mu(i|k)$ and $\Delta s_i(k) \gg \Delta \delta_i(k)$. After about five simulation steps, $\Delta s_i(k)$ drops to a flat plateau, which is approximately equal to $s_i(k)$. At any time $t$, one observes that $\Delta \delta_i(k) \ll \Delta s_i(k)$.

One may also model $L(z_k) = T(z_k) - B(z_k)$ as a function of cell index of the cells. In the one-dimensional model with $N = 50$, Fig. 6 compares $L(k)$ determined by the simulation, and $\hat{L}(z_k)$ predicted by Eq. (10) as the snowflake grows from the origin $\mathcal{O}$ to the edge cell. For any $k$, one observes that $L(z_k) < \hat{L}(z_k)$. This phenomenon is expected, since by solving the above PDEs one has that there exists $\alpha > 0$ such that at any time instance $t \in [B(z_k), T(z_k)]$, for $i = k, \ldots, N$, one has

$$\mu(i|k) \leq s_i(z_k) and \Delta \delta_i(z_k) \leq \Delta s_i(z_k).$$

As a result, $\hat{L}(z_k) \geq L(z_k)$. Equation (10) predicts that $\hat{L}(z_k)$ drops monotonically with $k$. In simulation, we observe that in the beginning the cells grow from boundary to frozen very quickly, well before the steady state is reached. As a result, the steady state Assumption IV does not hold in that time period. Figure 6 shows that $L(z_k)$ first increases, then drops, and eventually matches the prediction $\hat{L}(z_k)$.

Finally, we return to the two-dimensional hexagonal cellular case. With a similar steady state assumption, we can reduce the PDE to a set of linear equations similar to Eq. (7). However, the geometric structure is much more complex than the one-dimensional case. As a result, it is difficult to derive a closed form formula of the vapor distribution similar to Eq. (8).

Figure 7 plots $L(0,j)$ along a main branch. Comparison with Fig. 6 indicates a similarity between the one-dimensional and two-dimensional cases in that $L(z)$ increases as the snowflake grows from the origin. However, in the two-dimensional case, we observe from simulations that $L(0,10) = L(0,11) = \cdots = L(0,195)$. When the snowflake grows close to the edge cell, it experiences some edge effect in the simulation where $L$ drops drastically. This indicates that
somewhat surprisingly $\Delta s_i(0,j)$ remains almost constant as the snowflake grows along the main branch.

V. GROWTH OF SIDE BRANCHES

While the main branches of snowflakes represent clean sixfold symmetry, the side branches exhibit characteristic features of chaotic dynamics: complexity and unpredictability. Reiter’s model is completely deterministic with no noise or randomness involved, and yet the resultant snowflake images are sensitive to the parameters $\alpha, \beta,$ and $\gamma$ in a chaotic manner. Chaos may appear to be the antithesis of symmetry and the horizontal and vertical axes.

Definition 5. Starting from a cell $z_0$ on the $j$-axis main branch, the set of consecutive frozen cells in the $i$-axis direction are referred to as side branch from cell $z_0$. We shall denote by $z_s(z_0)$ the outmost cell or tip, by $E(z_0)$ the length of the side branch, and the side branch itself by $\Phi(z_0) := \{z_0, \ldots, z_{E}(z_0)\}$.

In what follows, we study the growth latency of side branches. Figure 8 plots the tips of the side branches that grow from the $j$-axis main branch using the parameters of the four images in Fig. 3.

Due to the chaotic dynamics, the lengths of the side branches vary drastically with $z_0$ in a seemingly random manner. For image (a), most of the side branches are short and only a small number stand out. The opposite holds for image (d). The scenarios are in between for images (b) and (c). The length of the side branches is indicative of the growth latency. The long side branches represent the ones that grow almost as fast as the main branch, such that $\theta \approx \pi/3$ and the resultant image, appearing in Fig. 3(d), is roughly a hexagon.

We shall consider next the growth directions of the cells on side branches. Figure 9 plots the trace of the growth direction $g(z)$ (see Definition III) as a snowflake develops in the simulation. The corresponding snowflake image is shown in Fig. 3(b). When a cell $z$ becomes boundary, we mark the cell to indicate $g(z)$ using the legend labeled in the figure. If a cell never becomes boundary, no mark is made. All side branches grow from the $j$-axis main branch, starting in the direction parallel to the $i$-axis. Subsequently, a side branch may split into multiple directions. Indeed, all six orientations have been observed and the dynamics appear chaotic as $g(z)$ appears unpredictable. However, we do find an interesting pattern described below.

Definition 6. A straight path from a cell $z_0$ on the $j$-axis main branch is the set of consecutive frozen cells in the $i$-axis direction satisfying $z_{i-1} = S(z_i)$. The number of consecutive cells satisfying $z_{i-1} = S(z_i)$ is the length $F(z_0)$. We then denote a straight path from a cell $z_0$ by $\Psi(z_0) := \{z_0, z_1, z_2, \ldots, z_{F(z_0)}\}$.

Comparison between Definition V and Definition V shows that the paths are nested, i.e., $\Psi(z_0) \subset \Phi(z_0)$, and hence the lengths satisfy $F(z_0) \leq E(z_0)$. When a cell $z_{i-1}$ on the straight path becomes frozen, it triggers not only $z_i$ in the $i$-axis direction but also other neighbors to become boundary.
resulting in growth in other directions, which we call deviating paths. The straight and deviating paths collectively form a side branch cluster.

Definition 7. The set of frozen cells that can be traced back to a cell on the straight path from cell $z_0$ on the $j$-axis main branch is referred to as a side branch cluster and denoted by $\Theta(z_0)$.

A side branch cluster is a visual notion of a collection of side branches that appear to grow together. Figure 9 shows several side branch clusters and the cells on the corresponding straight path marked with cyan $\times$. Compared with the straight paths, the deviating paths do not grow very far, because they compete with other straight or deviating paths for vapor accumulation in diffusion. On the other hand, the competition with the deviating paths slows down or may even block the growth of a straight path. When a straight path is blocked, the straight path is a strict subset of the corresponding side branch. This scenario is illustrated in Fig. 10, where three side branches are shown.

The straight path of the middle side branch is blocked by a deviating path of the lower side branch, which grows into a sizable side branch cluster. Through the above definitions one has that if there exists a cell $z \in \Theta(z_0)$ and $z \notin \Phi(z_0)$, then the paths are nested $\Psi(z_0) \subset \Phi(z_0)$. Moreover, the straight path determines the length of the side branch cluster:

Definition 8. Denote by $D(z, z_0)$ the distance between $z_0, z \in \Theta(z_0)$, defined as the smallest number of sites on the lattice between $z$ and $z_0$. The length of $\Theta(z_0)$ is

$$D(z_0) := \max_{z \in \Theta(z_0)} D(z, z_0).$$

Through the above definition one can show that there are $K$ cells $z_i \in \Theta(z_0)$ such that the distances satisfy $D(z_i, z_0) = D(z_0)$ for $i = 1, \ldots, K$ with $K \geq 2$. Furthermore, there exists $z_i \in \Psi(z_0)$ for $1 \leq i \leq K$, and thus $D(z_0) = F(z_0)$, the length of $\Psi(z_0)$ as in Definition $V$.

VI. An Enhanced Reiter’s Model

Plates and dendrites are two basic types of regular, symmetrical snowflakes. We observe that while the dendrite images in Figs. 3(a) and 3(b) generated by Reiter’s model resemble quite accurately the real snowflake in Fig. 1(a), as seen in Figs. 3(c) and 3(d) and Figs. 1(b) and 1(c), the plate images differ significantly. The plate images in Figs. 3(c) and 3(d) is in effect generated as a very leafy dendrite. One of the reasons that Reiter’s model is unable to generate plate images realistically is that the model only includes diffusion, thus not taking into account the effect of local geometry.

As described in Ref. [12], two basic types of mechanisms contribute to the solidification process of snowflakes: diffusion control and interface control. Diffusion control is a nongeometric growth model, where snowflake surfaces are everywhere rough due to diffusion instability, a characteristic result of chaotic dynamics. For example, if a plane snowflake surface develops a small bump, it will have more exposure into the surrounding vapor and grow faster than its immediate neighborhood due to diffusion. Interface control is a geometric mechanism where snowflake growth only depends on local geometry, i.e., curvature related forces. In the small bump example, the surface molecules on the bump with positive curvature have fewer nearest neighbors than do those on a plane surface and are thus more likely to be removed, making the bump move back to the plane. Interface control makes snowflake surfaces smooth and stable, and it is illustrated in Fig. 11.

In summary, snowflake growth is determined by the competition of the destabilizing force (diffusion control) and stabilizing force (interface control). In the absence of interface control, Reiter’s model is unable to simulate certain features of snowflake growth.

The interface between the snowflake and vapor regions has potential energy, called surface free energy, due to the unfilled electron orbitals of the surface molecules. The surface free energy $\gamma(n)$ as a function of direction $n$, is determined by the internal structure of the snowflake, and in the case of a lattice plane is proportional to lattice spacing in a given direction.
The equilibrium shape of the interface is the one that minimizes the total surface free energy for a given enclosed volume. Wulff construction (see Ref. [12]) can be used to derive the equilibrium crystal shape \( W_n \) from the surface free energy plot \( \gamma(n) \):

\[
W_n := \{ r | r \cdot n \leq \gamma(n), \forall n \}. \tag{12}
\]

Wulff construction states that the distances of the equilibrium crystal shape from the origin are proportional to their surface free energies per unit area. Figure 12 plots the equilibrium crystal shape of snowflake. Moreover, it shows that due to interface control, snowflake growth is the slowest along the lattice axes, and the fastest along the 30\(^\circ\)-offset lattice axes.

This can be explained intuitively. Snowflakes grow by adding layers of molecules to the existing surfaces. The larger the spaces between parallel lattice planes, the faster the growth is in that direction. This effect is completely opposite to the diffusion control we have studied in Sec. IV, where snowflake grows fastest along the lattice axes. This is an example of competition between diffusion control and interface control.

We next propose a new geometric rule to incorporate interface control in Reiter’s model. The idea is that the surface free energy minimization forces the lattice points on an equilibrium crystal shape to possess the same amount of vapor so that the surface tends to converge to the equilibrium crystal shape as the snowflake grows. It should be pointed out that crystals that grow under the control of interfacial kinetic processes tend asymptotically toward a kinetically Wulff shape, the analog of the Wulff shape, except it is based on the anisotropic interfacial kinetic coefficient rather than the anisotropic surface free energy. The proposed model does not take into account the anisotropic interfacial kinetic coefficient based on a lateral motion of steps.

From Fig. 12, we learn that the equilibrium crystal shape is a hexagon except for six narrow regions along the 30\(^\circ\)-offset lattice axes where the transition from one edge of the hexagon to another edge is smoothed. The equilibrium crystal shape used in the new geometric rule is shown in Fig. 13.

Figure 13 shows the equilibrium crystal shape used in the new geometric rule and the interface control neighbors of the cells. As an example, cells A, B, C, D, E, F are the interface control neighbors of A, cells A, C are the interface control neighbors of B, etc.

The new geometric rule is applied after Eq. (5): A new variable \( \delta_i(z) \) is defined to represent the amount of water to be redistributed for cell \( z \) at time \( t \), with initial value \( \delta_i(z) = 0 \) for all \( z \).

Definition 9. For a given cell \( z_0 \), define two interface control neighbors \( z_0^1, z_0^2 \), which are two neighboring cells of \( z_0 \) on the same equilibrium crystal shape.

Define \( \overline{s}(z_0) \) as the average of the water amounts in cell \( z_0 \) and its two interface control neighbors \( z_0^1, z_0^2 \):

\[
\overline{s}(z_0) := \frac{1}{2}[s_{t+1}(z_0^1) + s_{t+1}(z_0^2) + s_{t+1}(z_0^3)] \tag{13}.
\]

For every boundary \( z_0 \), if neither of \( z_0^1, z_0^2 \) are frozen, then adjust \( \delta_i(z_0) \) as follows:

\[
\delta_i(z_0) = \delta_i(z_0) + \epsilon[\overline{s}(z_0) - s_{t+1}(z_0)]. \tag{14}
\]

\[
\delta_i(z_0^1) = \delta_i(z_0^1) + \epsilon[\overline{s}(z_0) - s_{t+1}(z_0^1)]. \tag{15}
\]

\[
\delta_i(z_0^2) = \delta_i(z_0^2) + \epsilon[\overline{s}(z_0) - s_{t+1}(z_0^2)]. \tag{16}
\]
is almost constant (Fig. 7) and whether this phenomenon is the main branch growth, one may ask why the growth latency patterns lead to further questions about crystal growth. On Reiter’s model.

For the solidification process, which is not present in the original model, we have introduced a new geometric rule to enhance the model, where the variables are (a) $\varepsilon \in \mathbb{R}_{>0}$ determines the amount of interface control. After $\delta_0(z)$ has been adjusted for all $z$ according to Eq. (14)–(16), for every cell $z$ set

$$s_{t+1}^z := s_t^z + \delta_0(z). \quad (17)$$

Recall that in the original Reiter’s model, once water is accumulated in a boundary cell, water stays permanently in that cell. The new function Eq. (17) forces water redistribution particularly among boundary cells to smoothen the snow vapor interface. Figure 14 shows two snowflake images generated by the enhanced Reiter’s model with the new geometric rule.

At $\varepsilon = 0.1$, the image above resembles a plate observed in nature much more closely than the ones in Fig. 3. By reducing interface control with $\varepsilon = 0.01$, the snowflake starts as a plate and later becomes a dendrite as diffusion control dominates interface control.

VII. CONCLUSIONS AND FUTURE WORK

In this paper we have analyzed the growth of snowflake images generated by a computer simulation model (Reiter’s model [10]) and have proposed ways to improve the model. We have derived an analytical solution of the main branch growth latency and made numerical comparison with simulation results. Subsequently we observed interesting patterns of side branches in terms of growth latency and direction. Finally, to enhance the model, we have introduced a new geometric rule that incorporates interface control, a basic mechanism of the solidification process, which is not present in the original Reiter’s model.

The present work has shed light into some interesting patterns that lead to further questions about crystal growth. On the main branch growth, one may ask why the growth latency is almost constant (Fig. 7) and whether this phenomenon is unique to the hexagonal cells or applicable to other two-dimensional lattices. Concerning the side branch growth, it was noted that some side branches grow much faster than their neighbors, and that with slightly different diffusion parameters the side branch growth latency could change drastically at the same position while the main branch growth latency remains virtually the same. The study in Sec. VI shows that this great sensitivity is attributable to diffusion instability: When the growth of cells in some direction gains initial advantage over their neighbors, the advantage continues to expand such that the growth in that direction becomes even faster. It was noted in Sec. VI that diffusion instability is caused by competition among cells in diffusion, and thus the average number of contributing neighbors is a good indicator to explain diffusion instability. Finally, the enhanced model described in Sec. VI can be used to explore the interplay of diffusion and interface control. For example, one may simulate growth in an environment where the diffusion and interface control parameters vary with time so as to generate images similar to Figs. 1(b) and 1(c).

Recently Reiter’s model was used in the study of snowfall retrieval algorithms (e.g., see Refs. [16,17] and references therein), and it was suggested that other mechanisms of snowflake formation from ice crystals besides aggregation must be considered in snowfall retrieval algorithms. It is thus natural to ask whether the enhanced Reiter’s model constructed here may provide insights in this direction, as well as when considering crystal growth dynamics as in Ref. [18]. Moreover, since cellular automata models have been considered for numerical computations of pattern formation in snow crystal growth, it would be interesting to analyze the outcome of the implementation of the model presented here to the analysis done in Refs. [13,19].

Finally, the effects of lattice anisotropy coupled to a diffusion process have been studied in Ref. [20] to understand phase diagrams associated to crystal growth. Since this approach seemed useful recently from different perspectives (e.g., see Ref. [21] and references therein), it would be interesting to study the enhanced model constructed here from the perspective of Refs. [20,21].

ACKNOWLEDGMENTS

The research in this paper was conducted by J.L. under the supervision of L.P.S., as part of the Illinois Geometry Lab & MIT-PRIMES program. Both authors are thankful for the opportunity to conduct this research together and would also like to thank K. Libbrecht and N. Goldenfeld for helpful comments. The work of L.P.S. is partially supported by NSF Grant No. DMS-1509693.
